Spin waves (or magnons) [1–3] are collective magnetic excitations that can propagate in metals [4] and also in insulators [5]. Intensive research efforts have been made to investigate spin waves in yttrium iron garnet Y₃Fe₅O₁₂ (YIG) [6,7], which exhibits the lowest damping that is promising for low-power consumption magnonic devices [8–10]. Most previous works were conducted on bulk or thick YIG films where the Damon-Eshbach (DE) spin-wave chirality [11–13] is well known for magnetostatic surface spin waves as illustrated in Fig. 1(a). However, the DE spin-wave chirality was negligible [14] in the thin YIG films, which were recently achieved with high quality for on-chip magnonic devices [15,16]. We report a different type of spin-wave chirality scaled up in ultrathin YIG films, which we attribute to the interfacial Dzyaloshinskii-Moriya interaction (DMI) [17,18]. Very recently, domain wall motion in Tm₃Fe₅O₁₂ (TmIG) on gadolinium gallium garnet (GGG) suggested interfacial DMI consistent with the Rashba effect at oxide-oxide interfaces [19–21]. However, independent evidence for the DMI was not provided. Spin waves provide a prevailing methodology [22–28] for probing the DMI in metallic multilayers. DMI is the fundamental mechanism to form chiral spin textures, such as skyrmions [29–31]. Most previous studies on the interfacial DMI focus on measuring frequency shifts δf between counterpropagating spin waves (with wave vectors +k and −k) using Brillouin light scattering (BLS) [25,27] or all-electrical spin-wave spectroscopy (AESWS) [26,28]. It has been theoretically predicted that the interfacial DMI can generate not only a frequency shift, but also asymmetric group velocities [24]. So far, there has been no experimental observation of nonreciprocal spin-wave characteristics and group velocities induced by interfacial DMI in bare ultrathin YIG films on GGG.

In this Letter, we report chiral propagation of spin waves in a 7-nm-thick YIG film on a (111) GGG substrate [32].
The spin waves propagating in the chirally favored direction are found to be substantially faster than in its counter-direction as illustrated in Fig. 1(b). The asymmetry in group velocities \( \delta v_g \) is characterized by AESWS \([4,16,26,33]\) to be approximately 80 m/s. The chiral spin-wave velocities in YIG films can be accounted for by an interfacial DMI and a DMI constant of 16 \( \mu J/m^2 \) estimated from the experiments. By integrating different antennas, we vary the spin-wave wave vectors and obtain an asymmetric spin-wave dispersion that can be fitted well using the DMI constant extracted from the chiral spin-wave velocities. Five thin-film YIG samples with thicknesses of 7, 10, 20, 40, and 80 nm are investigated. The DMI-induced drift group velocity \( v_D^\text{DMI} \) and \( \delta v_g \) increase when the film thickness decreases, which demonstrates that the DMI in YIG is of interfacial type. We evidence the DMI in the ultrathin YIG films independently by BLS revealing nonreciprocal spin-wave dispersion relations. The DMI constants extracted from the BLS and the AESWS measurements performed on the 10-nm-thick YIG sample agree well. Our discovery makes chiral magnonics \([34-36]\) a realistic vision as bare YIG offers ultralow spin-wave damping and thereby enables the plethora of suggested devices that functionize for instance unidirectional power flow, magnon Hall effect, and non-trivial refraction of spin waves.

The YIG films were grown on GGG substrates by magnetron sputtering \([32]\). The damping parameter for the 7-nm-thick YIG film is extracted from the ferromagnetic resonance measurements to be \( \alpha = 6.4 \pm 2.1 \times 10^{-4} \) \([37]\). The DE spin-wave chirality \([11-13]\) \([\text{Fig. 1(a)}]\) is negligible when the thickness is 7 nm \([14]\). However, a new type of spin-wave chirality might arise in the presence of DMI where spin waves propagating in opposite directions not only show amplitude nonreciprocity and frequency shifts, but also chiral spin-wave velocities. They are attributed to a DMI-induced drift group velocity whose direction follows a right-handed rule \([\text{inset of Fig. 1(b)}]\). Figure 1(c) shows a high-angle annular dark-field image near the YIG or GGG interface. To measure the spin-wave group velocities, two nano-stripelines (NSLs) are integrated on the 7-nm-thick YIG film to excite and detect spin waves \([37,39]\). The spin-wave propagation distance \( s = 2 \mu m \). The spin-wave transmission spectra \( S_{12} \) \((S_{21})\) suggest that spin waves are excited by NSL2 (NSL1) and detected by NSL1 (NSL2), which is defined as \( +k \) \((-k)\) spin-wave propagating directions \([37]\). The measured spectra with an external field swept from \(-50\) to 50 mT are shown in Supplemental Material Fig. S3 \([37]\). Chiral propagation of spin waves is clearly observed with respect to the wave vector \( k \) and applied field \( H \). This chirality is manifested in the angle-dependent measurement shown in Fig. 2. Figure 2(a) shows angle-dependent spectra for \( S_{12} \) \(+k\), where clear asymmetry is observed. The transmission spectra show contrast oscillations that indicate the...
phase variation of propagating spin waves \[4,16,33\]. In Fig. 2(b), we show a single spectrum at 90°, where a peak-to-peak frequency span \( \Delta f_{\phi} \) is marked indicating a phase change of 2\( \pi \). According to
\[
v_g^{(+)} = \frac{d\phi}{dk} = \frac{2\pi \Delta f_{\phi}^{(+)}}{2\pi/\gamma} = \Delta f_{\phi}^{(+)} s, \quad (1)
\]
the group velocity \( v_g^{(+)} \) for \(+k\) spin waves is estimated as \( v_g^{(+)} \approx 312 \text{ m/s} \), and \( v_g^{(-)} \) for \(-k\) spin waves is estimated as \( v_g^{(-)} \approx 236 \text{ m/s} \). Interestingly, for \(-90°, \text{i.e., a reversed applied field } H, \text{ the situation is nearly mirrored (Fig. 2). This demonstrates that spin waves propagating in two opposite directions } (+k \text{ and } -k) \text{ exhibit different group velocities, which can be reversed by changing the sign of the applied field, and thereby chiral spin-wave velocities are observed.}

Figure 3 shows \( \delta v_g = v_g^{(+)} - v_g^{(-)} \) extracted from the field-dependent measurements \[37\] based on Eq. (1) as a function of the field applied in 90°. Near zero field, the group velocities are reciprocal. However, at positive fields \( S_{12} \) is faster than \( S_{21} \) and at negative fields \( S_{21} \) is faster than \( S_{12} \); i.e., chiral spin-wave velocities are observed \[37\]. The \( \delta v_g \) shows a distinctive step-like field dependence. Theoretical studies \[24\] have predicted that interfacial DMI can introduce a drift group velocity \( v_g^{\text{DMI}} \). We indeed observe \( v_g^{\text{DMI}} \) experimentally and extract \( v_g^{\text{DMI}} \) = 40.8 m/s by fitting the experimental results in Fig. 3 with an empirical equation,
\[
\delta v_g = 2v_g^{\text{DMI}} \tanh \left( \frac{H}{H_0} \right), \quad (2)
\]
where \( H_0 \) is a fitting field value above which the velocity difference saturates. The sign of \( v_g^{\text{DMI}} \) is determined by a chiral relation among three unit vectors, i.e., the film normal vector \( \hat{n} \), applied field \( \hat{H} \), and spin-wave vector \( \hat{k} \) [inset of Fig. 1(b)]. According to previous theoretical studies \[24,36\], one can write
\[
v_g^{\text{DMI}} = \frac{[(\hat{n} \times \hat{H}) \cdot \hat{k}] 2\gamma D}{M_S}, \quad (3)
\]
where \( D \) is the DMI constant, \( M_S \) saturation magnetization. At a positive field, for example, the drift group velocity is towards the \(+k\) direction and therefore the spin-wave group velocity in the \(+k\) direction is faster than in the \(-k\) direction. Consequently, \( \delta v_g \) shows a positive sign and is twice the \( v_g^{\text{DMI}} \). Based on Eq. (3) and considering an \( M_S = 141 \text{ kA/m} \) \[32\], we can deduce a DMI constant \( D = 16 \mu \text{J/m}^2 \). The origin of a finite \( H_0 \) is however unclear. It is not observed in the micromagnetic simulations \[40\] (green dashed line in Fig. 3) showing a sharp step-like field dependence \[37\]. Considering that the magnetization loop measured by the vibrating sample magnetometer \[37\] is not fully closed at low field, we speculate \( H_0 \) to be a finite field required to completely eliminate small domain structures induced by surface roughness.

To study the \( k \) dependence, we integrated coplanar waveguides (CPWs) on the 7-nm-thick YIG film \[37\]. Two distinct modes are observed and attributed to the k1 = 3.1 rad/\( \mu \text{m} \) and \( k_2 = 9.1 \text{ rad/\( \mu \text{m} \), identified by Fourier transformation} \[4,16,26,33,37\]. We summarize data from NSL and CPW samples in Fig. 4(a) and observe clear asymmetry. The spin-wave dispersion relation \( f(k) \) [Fig. 4(a)] is calculated based on
\[
f = \frac{\gamma \mu_0}{2\pi} \left[ \left( H + \frac{2A}{\mu_0 M_S} k^2 \right) \left( H + M_S + \frac{2A}{\mu_0 M_S} k^2 \right) \right]^{-\frac{1}{2}} \left[ [(\hat{n} \times \hat{H}) \cdot \hat{k}] \frac{\gamma D}{\pi M_S k} \right], \quad (4)
\]
where \( \gamma \) is the gyromagnetic ratio, \( A = 0.37 \times 10^{-11} \text{ J/m} \) the exchange stiffness constant \[41\], and \( t = 7 \text{ nm} \) the film thickness. The first term is the nonchiral contribution from the dipole-exchange spin waves \[42\] in a DE configuration \[11,41,43\]. The second term originates from the interfacial DMI. The chirality is determined by the vector relation \( (\hat{n} \times \hat{H}) \cdot \hat{k} \) and its amplitude is decided by the DMI strength \( D \). By taking the DMI constant \( D = 16 \mu \text{J/m}^2 \) extracted from \( \delta v_g \), the calculated dispersion relations agree reasonably well with the experimental data points [Fig. 4(a)]. We rotate \( H \) in the film plane with respect to \( k \) and measure \( \delta v_g \) as a function of \( \theta \) [Fig. 4(b)]. The sinusoidal angular dependence is observed consistent with the vector relation \( (\hat{n} \times \hat{H}) \cdot \hat{k} \). In addition to the 7-nm-thick YIG film, we also measured spin-wave propagation in YIG films with other thicknesses \[37\]. The thickness dependence of \( \delta v_g \) is shown in Fig. 4(c), where the asymmetry in group velocities enlarges with decreasing thickness. The observed thickness dependence is opposite...
to that of the surface anisotropy-induced nonreciprocity [37,44,45]. This observation indicates that the observed DMI is an interfacial effect. The DMI constant $D$ can then be expressed as $D = (\lambda D) / t$ [26], where $D_i$ is the interfacial DMI parameter and $\lambda$ is the characteristic length of the interface, which depends on the details of the interface, such as roughness. With a rough estimation of $\lambda$ being the lattice constant of YIG $\alpha = 12.4$ Å [46] and a linear fitting of Fig. 4(c), we derive an interfacial DMI parameter $D_i = 90 \mu J/m^2$. The DMI-induced frequency shifts $\delta f$ [25–27] are also observed [37].

The transmission spectra shown in Fig. 2 exhibit a clear amplitude nonreciprocity. The nonreciprocity parameter $\beta = (S_{12} - S_{21}) / (S_{12} + S_{21})$ [47] is extracted as a function of $\theta$ [Fig. 4(d)]. At $\theta = 90^\circ$, $\beta$ increases when films go thicker [37] due to the DE nonreciprocity [14]. The remaining sizable amplitude nonreciprocity for 7-nm-thick YIG film may also result from the asymmetric decay of propagating spin waves [48], but most likely due to the excitation characteristics given by the antenna [12,49]. Interestingly, an unexpected increase of nonreciprocity occurs around $30^\circ$ [Fig. 4(d)] [37], which may result from the interfacial DMI. The spin-wave dispersions at $30^\circ$ become rather flat and therefore only a small group velocity $v_g^0$ remains [37,42,43,50]. If the DMI-induced drift group velocity $v_{g,DMI}^0 \approx v_{g,0}^0$, the nonreciprocity is enhanced due to the interfacial DMI [37,51].

We confirmed the interfacial DMI in ultrathin YIG films independently by BLS. The BLS spectra measured on the 10-nm-thick YIG showed clear frequency shifts $\delta f$ between the Stokes and anti-Stokes peaks [37], indicating an asymmetric dispersion $f(k)$ induced by the DMI. We extract $\delta f$ from the BLS data and plot them as a function of the spin-wave wave vector $k$ in Fig. 5, where $\delta f$ increases with an increasing $k$. This is consistent with the linear relationship given by $\delta f = (2\mu M_S)Dk$ [23–27]. Fitting the $k$-dependent frequency shifts we extract a DMI constant of $10.3 \pm 0.8 \mu J/m^2$ for the 10-nm-thick sample. This value is in good agreement with $9.9 \pm 1.9 \mu J/m^2$ extracted from the chiral spin-wave velocities measured by the AESWS [Fig. 4(c)]. The BLS spectra taken on a 7-nm-thick YIG film exhibit a small signal-to-noise ratio [37]. Still we observe a clear frequency shift of up to about 0.15 GHz at $k = 13.3$ rad/μm that yields a DMI constant of $14.2 \pm 4.2 \mu J/m^2$.

We now discuss the origin of the interfacial DMI in ultrathin YIG films. In general, the interfacial DMI stems from the inversion symmetry breaking in the film normal direction $\hat{n}$ and the spin-orbit coupling. In these samples, the upper surface is either exposed to air or covered by antennas. The observed effect does not change with different adhesion layers [37], which indicates that the DMI does not originate from the top but from the bottom surface of YIG consistent with TmIG/GGG samples reported recently [19–21]. The DMI may be enhanced by a heavy metal layer [52,53] on YIG, but consequently the damping is severely affected [54]. The energy dispersive x-ray spectroscopy and geometric phase analysis [37] are conducted and no significant Gd diffusion [55] is found in the 7-nm-thick YIG film grown by sputtering. Oxide interfaces are demonstrated experimentally to exhibit Rashba splitting, for example, in LaAlO$_3$/SrTiO$_3$ [56]. The Rashba-induced DMI is predicted at oxide-oxide interfaces [57] and is
further demonstrated by simulations to form chiral magnetic textures, such as skyrmions [58]. It has been manifested by first-principles calculations that Rashba-induced DMI exists in graphene-ferromagnet interface [59], even without strong spin-orbit coupling. For semiconductor heterostructures consisting of materials with different band gaps it is reported that the band offsets in conductance (and valence bands) are relevant for the Rashba effect [60]. The insulators YIG and GGG exhibit different band gaps [61] and corresponding band offsets are likely. To fully understand the origin of the interfacial DMI at the YIG/GGG interface, more studies such as first-principles calculations [59,62] and x-ray magnetic dichroism [63,64] are required, which are beyond the scope of this work. It would also be instructive to study the substrate dependence of the spin-wave nonreciprocity. However, it proves to be highly challenging to fabricate low-damping YIG on conventional substrates, such as Si [65] and GaAs [66]. The non-reciprocity effect induced by the dipolar interaction between top and bottom layers should be negligible since the parallel magnetic configuration can be established with a small field [37,67].

To summarize, we have observed chiral spin-wave velocities in ultrathin YIG films induced by DMI attributed to the YIG/GGG interface. The drift group velocity is about 40 m/s, yielding a DMI constant of 16 μJ/m². The chirality is ruled by the vector relation (\(\mathbf{\hat{n}} \times \mathbf{\hat{H}}\) · \(\mathbf{\hat{k}}\), verified by angle-dependent measurements. The DMI-induced chiral propagation of spin waves in the magnetic insulator YIG offers great prospects for chiral and spin-texture-based magnonics [68–71].
